The Baculovirus/Insect Cell System as an Alternative to Xenopus Oocytes

FIRST CHARACTERIZATION OF THE AKT1 K\(^+\) CHANNEL FROM ARABIDOPSIS THALIANA*

(Received for publication, February 13, 1996, and in revised form, May 31, 1996)

Two plant (Arabidopsis thaliana) K\(^+\) transport systems, KAT1 and AKT1, have been expressed in insect cells (SF9 cell line) using recombinant baculoviruses. Microscopic observation after immunogold staining revealed that the expressed AKT1 and KAT1 polypeptides were mainly associated with internal membranes, but that a minute fraction was targeted to the cell membrane. AKT1 was known, from earlier electrophysiological characterization in Xenopus oocytes, to be an inwardly rectifying voltage-gated channel highly selective for K\(^+\), while similar experiments had failed to characterize AKT1. Insect cells expressing AKT1 displayed an exogenous inwardly rectifying K\(^+\) conductance reminiscent of that described previously in Xenopus oocytes expressing AKT1. Under similar conditions, cells expressing AKT1 showed a disturbed cell membrane electrical stability that precluded electrophysiological analysis. Use of a baculovirus transfer vector designed so as to decrease the expression level allowed the first electrophysiological characterization of AKT1. The baculovirus system can thus be used as an alternative method when expression in Xenopus oocytes is unsuccessful for electrophysiological characterization of the ion channel of interest. The plant AKT1 protein has been shown in this way to be an inwardly rectifying voltage-gated channel highly selective for K\(^+\) ions and sensitive to cGMP.

In plants, inwardly rectifying potassium channel activity is involved in long-term K\(^+\) uptake and in related functions at the cell or whole plant level, e.g. (turgor regulation, stomatal guard cell movements, or cell expansion and plant growth (1–3). The first plant K\(^+\) channels characterized at the molecular level, AKT1 (4) and KAT1 (5) from Arabidopsis thaliana, were cloned by functional complementation of yeast strains defective in K\(^+\) transport. Several K\(^+\) channels have since been identified using probes from AKT1 or KAT1 cDNAs (Refs. 6–8 and sequences found in the EMBL Data Bank). These channels share strong homologies (>60% identity) and show structural and sequence homologies with K\(^+\) channels of the Shaker family found in insects and mammals (4, 5, 9). They display the characteristic hydrophobic domain consisting of six transmembrane segments, named S1 to S6, with a pore-forming region located between S5 and S6. A putative cyclic nucleotide-binding domain is present downstream of S6, as found in cyclic nucleotide-gated channels of the Shaker superfamily (4–8). Two subfamilies can be defined according to the presence or absence (channels of the AKT1 or KAT1 type, respectively) of an ankyrin domain in the polypeptide chain downstream of the putative cyclic nucleotide-binding domain (3, 4).

Electrophysiological characterization by heterologous expression in Xenopus laevis oocytes or yeast indicated that AKT1 is an inwardly rectifying voltage-gated K\(^+\) channel highly selective for K\(^+\) (10–15). It is expressed in guard cells and thought to mediate long-term K\(^+\) influx leading to stomatal opening (16). Northern blot analysis indicated that AKT1 is expressed mainly in roots (17). Studies of its tissue-specific expression using the GUS reporter gene revealed that its promoter directs preferential expression in the peripheral cell layers of the mature region of roots (18), suggesting a role in K\(^+\) uptake from the soil solution. Injection of AKT1 cRNA in Xenopus oocytes did not, however, affect the membrane conductance. The K\(^+\) channel activity of the encoded polypeptide thus awaited characterization.

The insect cell line SF9 can express high levels of foreign proteins when infected by a recombinant baculovirus. This expression system has been shown to be capable of performing most eukaryotic post-translational modifications (19, 20). It has been used, in particular, for expressing the Drosophila Shaker K\(^+\) channel in a functional form (21–23). In this study, functional expression of AKT1 and KAT1 polypeptides has been achieved using the baculovirus/SF9 system.

EXPERIMENTAL PROCEDURES

Antibodies—Polyclonal antibodies were raised against the ankyrin domain of AKT1 and the C-terminal region of KAT1 (see Fig. 1A). Nucleotide sequences coding for these domains were cloned into the pET-3c vector designed for expression in Escherichia coli (24). The required restriction sites (Ndel and BamHI) were introduced in AKT1 and KAT1 cDNAs as described below. The ankyrin domain of AKT1 was amplified by polymerase chain reaction using a 5’-primer (5’-TTTCATATGGATCTTCCTC) introducing a Ndel site at position 1600 of AKT1 cDNA and a 3’-primer (5’-GGAAACCAGATCCCGGTTAGTGTTAT) introducing a TAA stop codon at position 2218, just before the unique BamHI site present in AKT1. The Ndel-BamHI fragment was sequenced on both strands. AKT1 cDNA was introduced into pBlueScript® so that the BamHI polylinker site was present downstream of the KAT1 stop codon. The

Expression of Plant K⁺ Channels in Insect Cells

Nsl1-BamHI fragment encoding the C-terminal part of KAT1 was cloned into the MDR194 vector (25). Introducing a Ndel site just upstream of the NsiI site. The Ndel-BamHI fragment was thereafter introduced into the pET3c vector.

The recombinant pET3c vectors were introduced in E. coli strain BL21(DE3) (24). Protein expression was induced by adding isopropyl-1-thio-β-D-galactopyranoside (final concentration of 0.4 mM) and lasted 3 h at 37 °C.

The recombinant virus was used to transfect SF9 cells at 100,000 cells/ml and infected with recombinant baculovirus as described above (see “Membrane Purification”) and harvested 2 days later by pelleting at 500 × g for 5 min. They were fixed for 1 h in 4% paraformaldehyde in PBS at 4 °C. Following dehydration (increasing ethanol concentration up to 100%), cells were embedded in LR white resin (Taab). Thin sections were made and immunostaining was performed as described (31).

Micropipettes were two-step pulled from soft glass (Modulohm A/S, Herlev, Denmark) and displayed typically a 2-megaohm resistance in bath solution when filled with 80 mM KF, 50 mM KCl, 1 mM MgCl₂, 10 mM EGTA, 10 mM MOPS/NaOH (pH 7.2), and NaCl (osmolality set to 0.30). Reference and measuring electrodes were connected to an Axopatch 200 A amplifier that was controlled by pClamp software (Axon Instruments, Inc.). Linear leak current was digitally subtracted from recorded whole cell current. Most capacitative currents could usually be compensated by using built-in features of the amplifier. Residual capacitative currents were recorded digitally subtracted from whole cell currents using the method described by Zittel and Walther (33). Digitized data were analyzed using pClamp and SigmaPlot (Jandel Scientific, Erkrath, Germany) software.

RESULTS

Expression of KAT1 and AKT1—SF9 cells were infected either with wild-type baculovirus or with viruses recombinant for KAT1 or AKT1 cDNA: RB34T-KAT1, RB34T-AKT1, and RB217A-AKT1 (see “Experimental Procedures” and Fig. 1).

Membrane Purification—SF9 cells in exponential phase were layered at a density of 5 × 10⁶ cells/ml and infected with recombinant baculoviruses at a multiplicity of infection of 10. After 2 days of incubation at 28 °C, cells were harvested and centrifuged at 500 × g for 5 min. The pellet was washed with ice-cold PBS. The cells were centrifuged for 5 min at 500 × g and resuspended at 10⁶ cells/ml in a grinding medium containing 10 mM Tris-HCl (pH 7.5), 1 mM EDTA, 250 mM NaCl, 1% glycerol, 1 mM diithiothreitol, 2 mM phenylmethylsulfonyl fluoride, 2 μg/ml aprotinin, 1 μg/ml leupeptin, 1 μg/ml pepstatin, and 1 μg/ml antipain. The suspension was frozen in liquid nitrogen, quickly thawed at room temperature, and sonicated three times for 10 s with a probe sonicator. The homogenate (referred to as total extract) was centrifuged twice at 13,000 × g for 20 min. The supernatant was collected and centrifuged at 100,000 × g for 1 h. The crude membrane pellet was suspended in 2 mM Tris-HCl (pH 7.5), 1 mM diithiothreitol, 2 mM phenylmethylsulfonyl fluoride, and 1% glycerol and stored in liquid nitrogen. Proteins were assayed according to Schaffner and Weissman (29) using bovine serum albumin as a standard.

Immunoblotting—Proteins were separated by SDS-PAGE according to Laemmli (30) and electroblotted onto a nitrocellulose membrane (Schleicher & Schuell, Keene, NH) at 100 V for 1 h in a medium containing 25 mM Tris, 192 mM glycine, 0.1% SDS, and 20% methanol. Blots were blocked in PBS containing 5% low fat milk for 3 h at room temperature. Primary antibody diluted in PBS containing 0.1% Tween 20 (PBS-T) was bound overnight at room temperature. After three 10-min washes in PBS-T, goat anti-rabbit IgG secondary antibody coupled to peroxidase (Sigma) diluted in PBS-T was added. Blots were incubated for 2 h at room temperature and washed as described above. Peroxidase activity was detected using a 0.5 mg/ml 4-chloronaphthol solution prepared in PBS, 20% hydrogen peroxide, and 0.01% H₂O₂.

Immunogold Staining and Microscopy—SF9 cells were infected with recombinant baculoviruses as described above (see “Membrane Purification”) and harvested 2 days later by pelleting at 500 × g for 5 min.

Patch-Clamp Experiments—SF9 cells were plated in 3-cm diameter cell culture dishes and infected as described above (see “Membrane Purification”). Prior to electrophysiological recordings, culture medium was replaced by a bath solution containing 10 mM KCl (or 100 mM KCl), 4 mM CaCl₂, 5 mM MgCl₂, 5 mM glucose, 10 mM MES/Tris (pH 6.3), and NaCl (to give an osmolality of 0.28). Standard voltage-clamp protocols (see “Results”) allowed macroscopic current recording in the whole cell configuration of patch-clamp (32).

Plant Channel Targeting in SF9 Cells—In a preliminary biochemical approach, the cellular localization of plant channels expressed in SF9 cells was investigated by preparing soluble and membrane protein fractions and analyzing their polypeptide composition by SDS-PAGE. Polypeptide bands of the size expected for KAT1 or AKT1 cDNA, the polyhedrin band was no longer present, while an extra major band was clearly visible. The relative molecular mass of this band was close to that expected for the corresponding plant channel: ~70 kDa for KAT1 (predicted molecular mass of 78 kDa) and 95 kDa for AKT1 (predicted molecular mass of 97 kDa) (Fig. 2A). Antibodies raised against KAT1 or AKT1 detected a 70-kDa band (Fig. 2B, lane 34T-KAT1) and a 95-kDa band (lanes 34T-AKT1 and 217A-AKT1), respectively. This confirmed that both plant channels were expressed in SF9 cells. The level of expression of AKT1 was lower in RB217A-AKT1-infected cells than in RB34T-AKT1-infected cells, as expected from the use of an 8 base pair-deleted polyhedrin promoter (28).

2 The abbreviations used are: PAGE, polyacrylamide gel electrophoresis; PBS, phosphate-buffered saline; MES, 4-morpholinethane-sulfonic acid; MOPS, 4-morpholinopropanesulfonic acid.
control cells (uninfected or infected with wild-type virus) (data not shown). Strong staining was observed in both RB34T-AKT1- and RB217D-AKT1-infected cells (Fig. 4, A–D), in contrast to control cells. Additionally, KAT1-expressing cells (RB34T-KAT1-infected) probed with the serum raised against the AKT1 ankyrin domain (Fig. 4E) also showed little staining, equivalent to that observed with the other controls. High magnification micrographs (Fig. 4, C–D) indicated that most AKT1 proteins had an intracellular localization in both cells and that only a minute fraction of the expressed polypeptide was targeted to the plasma membrane. The intracellular pool of AKT1 was associated with internal membranes. Counting of gold particles was performed on nine different cells of each type. While internal membrane staining in RB217D-AKT1-infected cells was 35% lower than in RB34T-AKT1-infected cells (24 and 37 particles/\(\mu m^2\), respectively; S.D., 20% of mean values), plasma membrane staining was similar in both cell types (2.7 ± 0.8 particles/\(\mu m^2\) of plasma membrane) (data not shown).

FIG. 1. Construction of E. coli expression vectors and of baculovirus transfer vectors. A, KAT1 and AKT1 cDNAs (EMBL Data Bank accession numbers X93022 and X62907) flanked by NotI sites, obtained by NotI digestion of clones isolated from the yeast expression A. thaliana cDNA library (41). Black box, cDNA domain encoding the channel hydrophobic core including the six membrane-spanning segments; gray box, cGMP-binding domain; striped box, ankyrin (ANKY) domain of AKT1 (for sequence analysis, see Refs. 4 and 9). The C-terminal region of KAT1 and the ankyrin domain of AKT1 were expressed in E. coli using the pET-3c vector, the coding sequences being introduced between the NotI and the BamHI cloning sites (see “Experimental Procedures”). The positions of the KAT1 and AKT1 initiator ATG and stop codons and those of the restriction sites used for this work are indicated. The C-terminal region of KAT1 expressed in E. coli begins at the NotI site present at position 1604 and ends with the stop codon of the protein. To produce the ankyrin domain of AKT1, an NotI site (underlined) and a stop codon just upstream of the BamHI site were introduced by polymerase chain reaction. B, diagrammatic representation of the transfer vectors used to obtain recombinant baculoviruses. KAT1 and AKT1 cDNAs were cloned downstream of the promoter of the baculovirus polyhedrin gene. Numbering is given using position +1 for the first nucleotide of the polyhedrin initiator ATG codon. WT, wild-type baculovirus polyhedrin gene region. Gray and black boxes, the promoter and open reading frame, respectively, of the polyhedrin gene. p34T-KAT1 and p34T-AKT1 are transfer vectors obtained by cloning KAT1 and AKT1 cDNAs into pGmAc34T, respectively. p217Δ-AKT1 was obtained by cloning AKT1 cDNA into pGmAc217. BglII sites were introduced upstream of the initiator codon and downstream of the stop codon of AKT1 by polymerase chain reaction.

FIG. 2. Expression of KAT1 and AKT1 in Sf9 cells. Lanes NI and WT, total extract from uninfected cells and wild-type baculovirus-infected cells, respectively; lanes 34T-KAT1, 34T-AKT1, and 217Δ-AKT1, total extract from cells infected with RB34T-KAT1, RB34T-AKT1, and RB217Δ-AKT1, respectively. A, Coomassie Blue-stained gel. Extracts (60 \(\mu g\) of protein) were subjected to SDS-PAGE (8–15% polyacrylamide gel). The positions of AKT1 and KAT1 are indicated by arrowheads. B, Western blots. Lanes NI and WT contained 10 \(\mu g\) of protein. Lanes 34T-KAT1, 34T-AKT1, and 217Δ-AKT1 contained 2 \(\mu g\) of protein. Blots were probed using a serum directed against the ankyrin domain of AKT1 (left) or a serum directed against the C-terminal part of KAT1 (right) (see Fig. 1).
Expression of Plant K⁺ Channels in Insect Cells

Electrophysiological Evidence for Functional Channel Expression—From a holding potential of −10 mV, membrane potential was clamped for 800-ms periods to values ranging from 0 to −160 mV. Negligible currents were usually recorded in cells infected with wild-type virus as shown in Fig. 5A. In some cell batches, however, randomly activating currents could be recorded at membrane potential values negative to −120 mV (data not shown). Cell batches that exhibited this behavior were discarded.

Slowly activating inward currents could be recorded in cells infected with each of the recombinant viruses (Fig. 5, B–D). During double-pulse protocols, the above three cell types displayed tail currents that reversed at potential values close to the equilibrium potential for K⁺ ions. As current recording was much more reproducible in cells expressing AKT1 from RB217 compared with RB34T-AKT1 (Fig. 5C), AKT1 channel activity was further characterized using the former virus.

AKT1 Channel Voltage Gating—Inward currents were recorded during hyperpolarizing pulses in cells bathed first in 10 mM K⁺ and thereafter in 100 mM K⁺. These currents activated slowly with a multiexponential time course (Fig. 7, A and B). Steady-state activation was virtually achieved within the 1100-ms hyperpolarizing pulses. Half-activation time was clearly voltage-dependent: 40 ms at −180 mV and 160 ms at −120 mV in the 10 mM K⁺ bath (36 and 140 ms, respectively, in 100 mM K⁺). Plotting steady-state current versus voltage (Fig. 7C) revealed a strong inward rectification. Due to the presence of a Shaker S4-like voltage sensor in AKT1 (4), we hypothesized that this rectification was due mainly to a voltage-dependent G/Gmax ratio and determined whether the steady-state I/V curves shown in Fig. 7C could be fitted by a simplified voltage-gating model. As described previously for the KAT1 channel (12), the steady-state current was assumed to be predicted by the Goldman equation, multiplied by a voltage-dependent G/Gmax ratio changing from 0 to 1 upon hyperpolarization. The G/Gmax voltage dependence was described using a simple two-state Boltzmann equation, assuming it was independent of the K⁺ concentration in the bath (10 or 100 mM). The calculated steady-state I/V curve was drawn in full line in Fig. 7C for each bath condition. The single Boltzmann curve corresponding to both fits is shown in Fig. 7D. The half-activa-
Effect of ATP and cGMP on AKT1 Activation—In most cases, a rapid decrease in AKT1 current was observed when the pipette solution contained no ATP (Fig. 8A). This decrease could generally be prevented by including 2 mM ATP in the pipette solution (Fig. 8B). The standard pipette solution thus contained 2 mM MgATP. In some cases, this ATP concentration caused an increase in the current recorded at a given potential. This was due to a slight positive shift in the activation potential (Fig. 8B). When the clamped cell was perfused with a bath solution supplemented with 0.1 mM 8-bromo-cGMP, the current decreased. This was due to a negative shift in the activation potential, as shown in Fig. 8C (example representative of six independent recordings). This shift in AKT1 activation potential was time-dependent; the maximal value was reached within ~5 min and was in the −25 to −40 mV range.

DISCUSSION

Our current knowledge of the structure/function relationship of voltage-gated animal Shaker channels originates mainly from the literature reporting the functional characterization of wild-type and mutant channels expressed in Xenopus oocytes. This expression system is popular for electrophysiologists as it is readily amenable to current recordings. However, in some unpublished experiments aimed at characterizing new putative animal channels, no functional expression has been obtained from cRNA injection in oocytes. Similarly, although the KAT1 channel was expressed and characterized in Xenopus oocytes (10–14), similar attempts for AKT1 have failed up until now.

The baculovirus/insect cell system has often been used to express functional membrane proteins (20). The Drosophila Shaker K⁺ channel was shown to be expressed in Sf9 cells and targeted to the plasma membrane in a functional state (21). KAT1 and AKT1 are the first ion channels from the plant kingdom to be expressed using this system.

Data for the reversal potential of the AKT1 current were obtained from instantaneous deactivating currents recorded after a 800-ms-long activating prepulse at −150 mV and are given as mean ± S.D. (number of determinations). The theoretical K⁺ equilibrium potential was derived from the Nernst equation, assuming that the cell K⁺ concentration is that of the pipette solution.

**Fig. 6.** Deactivating currents recorded in RB217A-AKT1-infected Sf9 cells and instantaneous current/voltage curve. The bath solution contained either 10 mM KCl (A) or 100 mM KCl (B). A and B, currents recorded during double-pulse protocols. Holding potential was 0 mV. The activating pulse at −150 mV lasted 800 ms. Tail currents were recorded in the −20 to −120 mV range in 10 mM K⁺ bath solution (A) and in the 40 to −60 mV range (10-mV step) in 100 mM K⁺ bath solution (B). Leak and capacitive currents were mathematically subtracted after recording. C, instantaneous deactivating current plotted against voltage applied during the second pulse of the voltage-clamp protocol. The data are from A (○) and B (●).
nels have been expressed in a functional form and partly targeted to the plasma membrane of the cells as revealed by whole cell current recording and immunogold staining (Figs. 4–8). This is the first report showing that the baculovirus expression system can be used in an alternative strategy for characterizing ion channels when attempts using Xenopus oocytes have failed. The reason why AKT1 is expressed in a functional state in the former system and not in the latter is still unknown.

The membrane of Sf9 cells was often unable to withstand hyperpolarizations beyond $-100 \text{ mV}$. Due to this problem, Sf9 cells do not offer the ideal system for electrophysiological characterization of hyperpolarization-activated channels such as KAT1 and AKT1. Some cell batches, however, were able to withstand membrane potential as negative as $-160 \text{ mV}$ (Fig. 5A) or even $-180 \text{ mV}$. It is worth noting that Sf9 cells infected with either RB34T-KAT1 or RB217Δ-AKT1 recombinant baculovirus withstood large hyperpolarizations (see Fig. 6 for RB217Δ-AKT1-infected cells) much more reproducibly than wild-type baculovirus-infected cells or RB34T-AKT1-infected cells.

AKT1 was highly expressed in cells infected with RB34T-AKT1 (Fig. 2); however, these cells showed membrane instability. Breakdowns occurred especially at potentials more negative than $-100$ to $-120 \text{ mV}$, precluding any characterization of AKT1 channel activity using this construct (Fig. 5C). As expected, the expression level of AKT1 in cells infected with RB217Δ-AKT1 was lower than in the former cells (Fig. 2). In both types of cells, the plant channel was present in the membrane fraction (Fig. 3), although the amount of AKT1 actually targeted to the plasma membrane was small and roughly the same in both cases (Fig. 4). Most expressed polypeptides remained associated with internal membranes; their functional competence is unknown. A similar phenomenon with the expression of the Drosophila Shaker channel in Sf9 cells was hypothesized from the discrepancy between the magnitude of the currents recorded in the infected cells and the intensity of the Shaker polypeptide band on a Coomassie Blue-stained protein gel (21). Similarly, a liver gap junction protein expressed in Sf9 cells has been shown to remain mainly associated with the endoplasmic reticulum, with only a small fraction reaching the cell surface (34). It seems that Sf9 cells are able to synthesize large amounts of membrane proteins, but the protein export machinery is overwhelmed by the high rates of synthesis (35).

By making use of the RB217Δ-AKT1 virus instead of the RB34T-AKT1 virus, it was possible to obtain conditions allowing the functional characterization of AKT1. This work represents the first data on AKT1 channel activity. Our results demonstrated that the reversal potential for AKT1 current remained close to the equilibrium potential for $K^+$ ions when the external concentration of this ion was changed (Table I), indicating that this current is mainly carried by $K^+$ ions. This is in agreement with the presence in the putative selectivity filter-forming region of a GYGD motif (4) thought to be a hallmark of highly selective $K^+$ channels (36).

Like KAT1 current, AKT1 current activated slowly upon hyperpolarization and underwent no inactivation (Fig. 5). Comparison of traces in Fig. 5D to those in Fig. 5B reveals that AKT1 activation was slower than that of KAT1 and occurred from a more negative threshold potential. It should be noted, however, that KAT1 activation in Sf9 cells was faster (half-activation time of $-15 \text{ ms}$ at $-140 \text{ mV}$) (Fig. 5B) than that observed in Xenopus oocytes (half-activation time of $-200 \text{ ms}$ at $-140 \text{ mV}$) (11). Thus, the kinetic features of KAT1 are dependent on the expression system used. This might be due to...
Boltzmann fit in Fig. 7D. The presence of ATP in the pipette solution was required to obtain routinely a stable AKT1 activation upon repeated hyperpolarizations. AKT1 current decrease in the absence of ATP was variable between cells (in the example of Fig. 5A, the decrease was particularly fast). ATP (2 mmol/liter) generally shifted the IV curve positively along the voltage axis (Fig. 5B). A shift of this curve in the opposite direction was elicited by bathing the cell with 100 μM 8-bromo-cGMP solution (Fig. 5C). All but one of these observations are reminiscent of those recently reported regarding KAT1 expressed in oocytes: while the decrease in KAT1 current was mainly due to a negative shift in the IV curve along the voltage axis (13), that of AKT1 originated from a decrease in activable channels (Fig. 5A). Previous sequence analysis indicated that a putative cyclic nucleotide-binding site sharing sequence homologies with the cyclic nucleotide-binding domain of animal cyclic nucleotide-gated channels is present in both AKT1 and KAT1 polypeptides, downstream of the membrane-spanning region (3, 4). The effect of cGMP on AKT1 and KAT1 activity may thus indicate direct modulation by cGMP, i.e. resulting from cGMP binding to the channel. An indirect effect cannot, however, be ruled out since modulation by cyclic nucleotide-dependent protein kinases is a likely means of K+ channel regulation in planta (38). Also, the hypothesis of an indirect effect is supported by the time dependence of the shift in activation potential.

The highest similarities between AKT1 and KAT1 and the animal K+ channels of the Shaker superfamily are found with the Drosophila Eag gene product. The Eag channel has been shown to be both voltage-dependent and cAMP-modulated (39). The existence of a link between strictly voltage-gated K+ channels and cyclic nucleotide-gated ion channels has been proposed (40). Eag, KAT1, and AKT1 may be members of a class of channels representing such a link.

In conclusion, we have shown that the baculovirus system can be used as an alternative method when expression in Xenopus oocytes is unsuccessful for electrophysiological characterization of the ion channel of interest. The plant AKT1 protein has been shown in this way to be a K+-selective, voltage-gated, and probably cGMP-modulated channel.

Acknowledgment—We thank Dr. David Logan for critical reading of the manuscript.
